Tackling Fairness, Change and Polysemy in Word Embeddings

> Felipe Bravo Márquez

Word Embeddings

- ► The first step in computationally working with written language is to represent words as mathematical objects we can operate with.
- Representing words as numeric vectors a.k.a embeddings is a standard practice in Natural Language Processing (NLP).
- Word embeddings are a mapping of discrete symbols (i.e., words) to continuous vectors.
- Distance between vectors can be equated to distance between words.
- ► This makes easier to generalize the behavior from one word to another.
- Word embeddings have become a core component of NLP downstream systems (e.g., sentiment analysis, machine translation, question answering).

Distributional Hypothesis

The construction of word embeddings from document corpora is based on the **Distributional Hypothesis** [Harris, 1954]: Words occurring in the same **contexts** tend to have similar meanings.

Or equivalently:

A word is characterized by the **company** it keeps.

The idea of word embedding is to map words occurring in similar contexts to similar vectors. Tackling Fairness, Change and Polysemy in Word Embeddings

Word Embeddings Algorithms

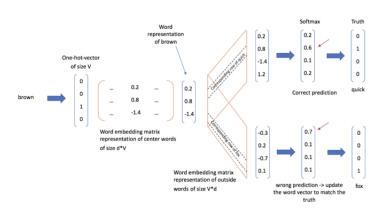

Tackling Fairness, Change and Polysemy in Word Embeddings

> Felipe Bravo Márquez

Introduction

- Word embeddings are build by training neural networks architectures on document corpora (e.g., books, papers, Wikipedia, tweets, the Web).
- These architectures formulate a predictive task (e.g., predict a missing word within a context window) in which word embeddings naturally arise from the network's parameters after training.
- Most popular models are:
 - Skip-gram negative sampling [Mikolov et al., 2013]
 - Continuous bag-of-words [Mikolov et al., 2013]
 - ► Glove [Pennington et al., 2014]
 - FastText [Bojanowski et al., 2016].

Limitations of Word Embeddings

- In this talk we will present our research addressing three limitations of word embeddings.
 - Fairness: they are prone to inherit stereotypical social biases from the corpus they were built on.
 - 2. **Change**: they are static. Thus they ignore words not observed during training and are unable to capture semantic drifts.
 - Polysemy: they fail to capture the polysemous nature of many words (e.g., apple:company, apple:fruit), conflating their multiple senses into a single point.

Fairness

Change

Polysemy

Word embeddings have shown to exhibit **undesirable associations** for certain social identity groups (e.g., gender, race, religion):

- Black is to criminal as caucasian is to police.
- Man is to doctor as woman is to nurse.
- Man is to computer programmer as woman is to homemaker.

Fairness Metrics

- WEAT [Caliskan et al., 2017]: measures the degree of association between two sets of target words and two sets of attribute words.
 - The original paper focused on biases regarding ethnicity (in relation to pleasant-unpleasant words) and gender (in relation to occupations).
- RND [Garg et al., 2018]: compares embeddings related to two different social groups against a set of neutral words.
 - The paper evaluated gender and ethnic biases in embeddings trained over different time periods.
- RNSB [Sweeney and Najafian, 2019]: measures the KL divergence between the negative sentiment probability of the embeddings and a uniform distribution.
 - The paper studied bias towards national origin identity terms such as American, Mexican, and Canadian.

WEFE: The Word Embeddings Fairness Evaluation Framework

- Although metrics have similar objectives they cannot be easily compared with each other.
- They operate with different inputs (e.g., pairs of words, sets of words, multiple sets of words).
- Their outputs are also incompatible with each other (e.g., reals, positive numbers, [0, 1] range).
- The Word Embeddings Fairness Evaluation (WEFE) is a framework for measuring and mitigating bias in word embeddings [Badilla et al., 2020].
- WEFE formalizes existing fairness metrics into a unified framework.

Fairness

Change

WEFE: The Word Embeddings Fairness Evaluation Framework

- It encapsulates the input words of these metrics into standard objects called queries.
- Then, proceeds to quantify the bias of word embeddings using these queries along with different fairness metrics.
- It also allows us to rank various embedding models by aggregating the previous scores.

WEFE Building Blocks

Target Sets: a set of words intended to denote a particular social group. For example:

$$T_{\text{women}} = \{w_{\text{she}}, w_{\text{woman}}, w_{\text{girl}}, \ldots\}, \tag{1}$$

$$T_{\text{men}} = \{ w_{\text{he}}, w_{\text{man}}, w_{\text{boy}}, \ldots \}, \tag{2}$$

Attribute Sets: a set of words representing some attitude, characteristic, trait, occupational field, etc. that can be associated with individuals from any social group.
For example:

$$A_{\text{science}} = \{w_{\text{math}}, w_{\text{physics}}, w_{\text{chemistry}}, \ldots\}, \tag{3}$$

$$A_{\text{art}} = \{w_{\text{poetry}}, w_{\text{dance}}, w_{\text{literature}}, \ldots\}.$$
 (4)

Query: a pair Q = (T, A) in which T is a set of target word sets, and A is a set of attribute word sets.
For example:

$$Q = (\{T_{\text{women}}, T_{\text{men}}\}, \{A_{\text{science}}, A_{\text{art}}\}). \tag{5}$$

WEFE Building Blocks

Tackling Fairness, Change and Polysemy in Word Embeddings

> Felipe Bravo Márquez

Fairness

- Queries are the main building blocks used by fairness metrics to measure bias of word embedding models.
- Fairness metrics encapsulated by WEFE are defined with a query template $s_F = (t, a)$, which is a pair of natural values with the cardinalities of sets \mathcal{T} and A
- We equip each metric with a total order relation \leq_F that establishes what is to be considered as less biased.
- That is, if

$$F(\mathbf{M_1}, Q) \leq_F F(\mathbf{M_2}, Q)$$

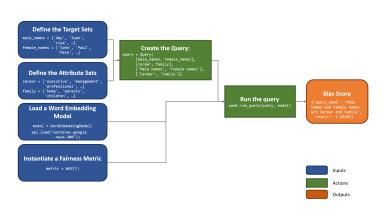

we can say that M_1 is less biased than model M_2 .

With this order relation we can rank various embeddings models according to their biases.

Incremental Word Vectors for time-evolving sentiment lexicon induction

- A sentiment lexicon is a list of expressions annotated according to affect categories such as positive, negative, anger and fear.
- Lexicons are widely used in sentiment classification of tweets.
- They are usually build by training a word-level sentiment classifier on pre-trained word embeddings using a **seed lexicon** as training data [Tang et al., 2014].
- However, as word embeddings are static by nature, sentiment lexicons build in this way are unable to capture:
 - 1. The arrival of new sentiment-conveying expressions such as #trumpwall and #PrayForParis.
 - Temporal changes in sentiment patterns of words (e.g., a scandal associated with an entity).

Change

Incremental Word Vectors for time-evolving sentiment lexicon induction

We developed a methodology for automatically inducing **continuously updated** sentiment lexicons from **Twitter streams** by training **incremental** word sentiment classifiers from **time-evolving word vectors**.

[Bravo-Marquez et al., 2021]

Tackling Fairness, Change and Polysemy in Word Embeddings

> Felipe Bravo Márquez

Introduction

Fairness

Change

Incremental Word Vectors for time-evolving sentiment lexicon induction

The process is summarized as follows:

- 1. Connect to a stream of continuously arriving text (e.g., Twitter).
- 2. Every time a new tweet arrives, a sliding window of *W* words centered on a target word is shifted across the content.
- The word vector associated with the target word is updated according to its context. This process implies updating word-context counts and computing PPMI-based associations.
- If the target word is new, a new vector associated with this word is created.
- If the target word is contained in the seed lexicon, the incremental classifier is updated/trained using the target word vector and the lexicon's sentiment as the gold label.
- If the target word is not contained in the lexicon, its sentiment is estimated using the classifier and the dynamic lexicon is updated.

PolyLM: a polysemous language model

 PolyLM is a language model capable of automatically learning multiple meanings of a word (e.g. apple:apple, apple:company)
 [Ansell et al., 2021].

(b) Sense embeddings

The occurrence of closely related polysemous words nearby in the word embedding space (i.e. left and right) causes unrelated words to be closer together (e.g. left and wrong) and related words to be further apart (e.g. right and east) than they otherwise would be Tackling Fairness, Change and Polysemy in Word Embeddings

> Felipe Bravo Márquez

Introduction

_.

PolyLM: a polysemous language model

PolyLM is an unsupervised language model based on two assumptions:

 The probability of a word occurring in a given context is equal to the sum of the probabilities of its individual senses.

$$p(w|c) = \sum_{s \in S_w} p(s|c). \tag{6}$$

- For a given occurrence of a word, one of its senses tends to be much more plausible in the context than the others.
- PolyLM is based on a Transformer encoder architecture and the masked language modeling (MLM) task used for training BERT.
- Its loss function combines a standard language modeling loss with a distinctness loss encouraging one sense to have a high estimated probability of occurring, and the rest to have a low probability.

Conclusions

- In this talk we have presented three research projects, each addressing a different limitation of word embeddings.
- I would like to thank all the co-authors of the presented works: Alan, Arun, Jorge, Pablo and Bernhard.
- There is plenty of room for further research.
